Debt, Innovation, and Growth

Thomas Geelen† Jakub Hajda‡ Erwan Morellec§

July 8, 2019

Abstract

Recent empirical studies show that innovative firms heavily rely on debt financing. This paper develops a Schumpeterian growth model in which firms’ dynamic R&D, investment, and financing choices are jointly and endogenously determined. It then investigates the relation between debt financing and innovation and growth. The paper features a rich interaction between firm policies and predicts substantial intra-industry variation in leverage and innovation, consistent with the empirical evidence. It also demonstrates that while debt hampers innovation by incumbents due to debt overhang, it also stimulates entry, thereby fostering innovation and growth at the aggregate level.

Over the last few decades, the US economy has become innovation driven. Public firms now spend twice as much on research and development than on capital expenditures and fixed assets have fallen from 34% to less than 20% of total assets between 1975 and 2016 (see for example Doidge, Kahle, Karolyi, and Stulz (2018)). Schumpeterian creative destruction has been a driving force of this transition to a knowledge-based economy. A good example of this phenomenon is Apple’s swift rise to power in the mobile phone industry, replacing Nokia as the market leader. This example of creative destruction was driven by Apple’s innovative success, even though both firms devoted large amounts of resources to R&D.

As shown in Figure 1, large firms play an important role for aggregate levels of innovation. Decades of empirical research have shown that outside debt is a key source of financing for these firms; see e.g. Graham, Leary, and Roberts (2015). In addition, even though debt is widely cast as an unlikely way to fund young and risky ventures, recent empirical studies show that small and young firms also heavily rely on debt financing. For example, Robb and Robinson (2014) find that formal debt financing (business bank loans, credit lines, and owner-backed bank loans) provide about 40% of a firm’s initial startup capital. The reliance on formal credit channels holds true even for the smallest firms at the earliest stages of founding. Looking only at those firms that access equity sources, such as venture capital or angel financing, the average firm still has around 25% of its capital structure in the form of outside debt. A recent study by Hochberg, Serrano, and Ziedonis (2017) further documents a

Figure 1: Innovation quality and intensity. The innovation data is based on Kogan, Papanikolaou, Seru, and Stoffman (2017) and the firm size data is from Compustat. The averages are conditional on issuing a new patent.
widespread use of loans to finance technology startups, even in early stages of developments. Relatedly, Davis, Morse, and Wang (2018) find that venture debt is often a complement to equity financing, with over 40% of all financing rounds including some amount of debt. Ibrahim (2010) estimates that venture lenders, including leader Silicon Valley Bank and specialized nonbank lenders, supply roughly $5 billion to start-ups annually.¹

Given the change to an innovation-based economy and the heavy reliance of innovative firms on debt financing, a number of questions naturally arise. First, how does debt financing influence the quality and intensity of innovation at the firm level? Second, how does debt financing affect firm growth, firm turnover, and industry structure? Third, how do innovation and Schumpeterian creative destruction in turn feed back into firms’ financing policies and leverage dynamics? Lastly, what are the implications of debt financing in innovative firms for creative destruction and aggregate levels of innovation and growth?

This paper attempts to answer these questions by developing a Schumpeterian growth model in which firms’ innovation, investment, and financing policies are endogenously determined. In this model, each incumbent has a portfolio of products and invests in R&D. Firms expand into new product lines when R&D is successful and lose some of their product lines to other firms through competition. The force of creative destruction therefore affects firms R&D policies, as each product remains profitable until it is overtaken by another firm’s innovation. Firms decide on both R&D intensity, that is the rate at which they generate new innovations, and R&D quality, that is the expected number of products that each innovation creates. Shareholders’ choice of R&D therefore determines firms’ cash flow dynamics, which feeds back into their financing decisions.

In the model, firms are financed with equity and debt and determine their optimal leverage ratio by balancing the tax benefits of debt against default costs and potential distortions in R&D and investment due to debt financing. The policy choices are such that firms that perform well releverage to exploit the debt tax shields embedded in shareholders’ equity stake. Firms that perform poorly default on debt and exit. Since debt and R&D policies are not ex-ante contractible, conflicts of interests between shareholders and debtholders distort

¹This literature generally shows that while it is the case that start-ups cannot typically obtain debt financing from traditional banks, major U.S. banking institutions, public firms, and private firms specialize in providing loans to the very start-ups that traditional banks turn away.
R&D and financing choices. The model implies specific investment and leverage dynamics for each firm, given the model parameters for the technology, tax, and legal environment.

After solving for individual R&D, investment, and financing choices, we embed the individual firm model into a Schumpeterian industry equilibrium in which the rate of creative destruction is determined endogenously. We derive a steady state equilibrium in which any new product line replaces an existing one and entrants replace incumbents that default and exit the industry. Firms in this equilibrium exhibit a wide variation in leverage, size, and innovation rates. Furthermore, all industry-wide equilibrium variables are constant over time, although individual firms continue innovating, investing, and adjusting their capital structure. In this equilibrium, capital structure and R&D influence each other through three main channels. First, R&D policy influences firms’ risk profile, which in turn affects their capital structure decisions. Second, leveraged firms can be subject to debt overhang, which alters their incentives to innovate. Third, firms’ individual R&D and capital structure decisions influence aggregate levels of creative destruction and therefore of competition, which feeds back into their individual policy choices.

Starting with firm-level policies, we find that there is significant interaction between leverage and innovation. Notably, high levels of debt lead to less innovation by incumbents due to debt overhang. The effect of debt on innovation is sizeable and larger for firms with fewer products. It is also larger for firms that face larger financing frictions. Moreover, R&D policies as well as the industry rate of creative destruction feed back in capital structure decisions. Crucially, firms’ R&D policy affect the rate of creative destruction and the probability of default. As a result, it plays a key role in determining firms’ capital structure choices. Our model thus features a rich interaction between R&D, investment, and financing decisions and predicts substantial intra-industry variation in leverage and innovation, consistent with the empirical evidence (see e.g. MacKay and Phillips (2005) and Kogan, Papanikolaou, Seru, and Stoffman (2017)).

A key result of the paper is to demonstrate that debt financing fosters innovation and creative destruction at the aggregate level. This is the outcome of two opposing forces. First, as discussed above, innovation and investment by incumbents are negatively associated with debt. This effect is quantitatively large in the static debt model, in which debt overhang is
severe. Allowing firms to refinance dampens these effects by allowing firms to take on less
debt initially. Second, while debt hampers innovation and investment by incumbents, it also
increases the value of incumbents and leads to a higher rate of creative destruction, which
increases the entry rate. We demonstrate that the latter effect dominates at the aggregate
level, implying that introducing debt financing in our endogenous growth model increases
innovation and creative destruction and fosters growth.

We also illustrate how conclusions reached in the single-firm model, when ignoring equi-
librium feedback effects, can be fundamentally altered, or even reversed, when the rate of
creative destruction is endogenized. Consider for example the effects of innovation costs on
equilibrium quantities. Increasing innovation costs leads to a drop in the level of innovation
and in the value of future innovations. This reduces the cost of debt and leads firms to
increase financial leverage. These effects are much stronger in a single-firm model that does
not incorporate the industry wide response. Indeed, an effect that is absent when ignoring
industry dynamics is that the drop in innovation quantity and the increase in leverage feed-
back into the equilibrium rate of creative destruction. As shown in the paper, the effect on
innovation is generally first order, leading to a negative relation between innovation costs
and the rate of creative destruction. This decrease in the rate of creative destruction—and
the corresponding increase in the expected productive life of product lines—spurs innova-
tion, partly offsetting the higher innovation costs. Lastly, these mechanisms translate to a
lower turnover rate as innovation costs increase, because the decrease in the rate of creative
destruction compensates for the lower levels of innovation. By contrast, in the single-firm
model in which industry feedback effects are ignored, the sharp increase in leverage due to
increasing innovation costs leads to an increase in the turnover rate.

Our article contributes to several strands of the literature. First, we contribute to the lit-
erature studying innovation in Schumpeterian growth models. Schumpeterian growth theory
has been widely used in the literature on innovation and industry structure and evolution;
see for example Klette and Kortum (2004), Lentz and Mortensen (2008), Aghion, Akcigit,
and Howitt (2014), Akcigit and Kerr (2018), and Acemoglu, Akcigit, Alp, Bloom, and Kerr
(2018). However, to the best of our knowledge, this literature has not studied the effects of
debt financing on innovation, Schumpeterian competition, and industry dynamics. This is
relatively surprising given that innovative firms heavily rely on debt financing. Our paper fills this gap by extending the model proposed by Klette and Kortum (2004) to incorporate debt financing.\(^2\) In our model, firms hold debt and default, which influences their R&D policies and the industry level of Schumpeterian creative destruction. Another departure from Klette and Kortum (2004) is that we introduce heterogeneity in the quality of innovations, which we show is key to match the patterns in Figure 1.\(^3\)

Second, our paper relates to the literature on dynamic capital structure choice initiated by Fischer, Heinkel, and Zechn (1989). Models in this literature generally maintain the Modigliani and Miller (1958) assumption that investment and financing decisions are independent by assuming that the assets of the firm are exogenously given. This allows them to focus solely on the liability side of the balance sheet (see for example Leland (1998), Goldstein, Ju, and Leland (2001), Strebulaev (2007), Morellec, Nikolov, and Schürhoff (2012), Glover (2016), Morellec, Nikolov, and Schürhoff (2017), or DeMarzo and He (2018)). Our paper advances this literature by endogenizing not only firms dynamic capital structure choices but also their investment policy. In line with the evidence in Chava and Roberts (2008), Giroud, Mueller, Stomper, and Westerkamp (2012), or Favara, Morellec, Schroth, and Valta (2017), we find that debt financing has a negative effect on innovation and investment at the firm level, due to debt overhang (Myers (1977)). The distortions in investment due to debt financing are large and imply important feedback effects of (endogenous) investment on dynamic capital structure choice. An additional contribution with respect to this literature is that we embed the individual firm choices into a Schumpeterian industry equilibrium. We show that while debt financing hampers investment at the firm level, it increases aggregate investment by stimulating creative destruction and entry.

Third, our paper relates to the literature on debt in industry equilibrium. Important contributions to this literature include Fries, Miller, and Perraudin (1997) and Zhdanov (2007), which respectively study static and dynamic capital structure choices in the Leahy

\(^2\)Klette and Kortum (2004), Lentz and Mortensen (2008), and Akcigit and Kerr (2018) show that this setup exhibits many behaviors consistent with the applied microeconomics literature.

\(^3\)Akcigit and Kerr (2018) also introduce heterogeneity in the Klette and Kortum (2004) model while maintaining the assumption that firms are all-equity financed. In their model firms choose their level of internal and external R&D, which leads to quality improvements on a single product of varying size. Instead firms choose the quality of innovations in our model, which determines the distribution over the number of products the firm improves.
(1993) model. In these models, incumbent firms are exposed to a single industry shock. They all have the same assets and the same debt level and there is no investment. In a closely related paper, Miao (2005) builds a competitive equilibrium model in which firms face idiosyncratic technology shocks and can issue debt at the time of entry before observing their profitability. In this model, all firms have the same debt level. However, the model has heterogeneity in firm size because firms are allowed to invest after entry. An important assumption in Miao (2005) is that there are no costs of adjusting capital. As a result, there is no debt overhang in the sense of Myers (1977) because the absence of adjustment costs or frictions make investment independent of financing (see also Manso (2008)). By contrast, in our model firms have different (endogenous) debt levels and can adjust capital structure after entry as profitability evolves. In addition, investment and financing decisions interact, leading to debt overhang and underinvestment by incumbents.

Another related paper is Kurtzman and Zaake (2018), who structurally estimate a general equilibrium model to quantify the aggregate implications of debt overhang on firms innovation activity and macroeconomic outcomes. In their model, innovations only temporarily boost productivity while innovations have a permanent impact in our model. This allows us to study the implications of debt financing on macroeconomic growth. Another important difference is that in our framework Schumpeterian creative destruction by competitors influences firms cash flow risk, which is a first-order determinant of their financing and investment decisions. Additionally, our model allows firms to choose not only innovation quantity but also innovation quality. Lastly, our model considers dynamic capital structure choice.

Finally, our paper relates to the growing literature on innovation and asset pricing. Important contributions to this literature include Garleanu, Panageas, and Yu (2012), Bena, Garlappi, and Grüning (2015), Kung and Schmid (2015), Kogan, Papanikolaou, and Stoffman (2018), or Garleanu and Panageas (2018). Most of these models are based on the expanding product variety model of Romer (1990), in which innovation is exogenous and there is no equilibrium feedback between R&D incentives and valuations. Because our focus is on the

\[4\text{In Miao (2005), firms underinvest in that levered firms exit the industry at a higher rate than unlevered firms would. This feature is also present in our model.}\]

\[5\text{In related research, Malamud and Zucchi (2017) develop a model of firms’ cash holdings, innovation, and aggregate growth in the presence of Schumpeterian competition. Their model assumes that firms are all equity financed.}\]
relation between debt financing and endogenous innovation and growth, we follow instead the recent endogenous growth literature discussed above by focusing on Schumpeterian competition. Importantly, Schumpeterian models can feature high competition and high economic growth, which is a key channel at work in our model.

This article is organized as follows. Section II describes an individual firm model and then embeds it into a Schumpeterian industry equilibrium. Section III analyzes the model implications for the relation between innovation and debt financing. Section IV closes the model in general equilibrium. Section V concludes. Technical developments are gathered in the Appendix.

I  Model

We present the model in steps, starting with the investment and financing decisions of an individual firm. We then embed the single-firm model into an industry equilibrium.

A  Assumptions

Throughout the paper, time is continuous and shareholders and creditors are risk neutral and discount cash flows at a constant rate $r > 0$. The economy consists of a unit mass of differentiated goods that are produced by incumbent firms.

A firm is defined by the portfolio of goods it produces. The discrete number of different products supplied by any given firm at time $t \geq 0$, denoted by $P_t$, is defined on the integers and is bounded from above by $\bar{p}$. As a result of competition between firms, each good is produced by a single firm and yields a profit flow of one. Its value and the profit flow of the firm evolve through time as a birth-death process that reflects product creation and destruction.

To increase the number of goods it produces, a firm invests in innovative effort, i.e. spends resources on R&D. A firm’s R&D choice is two-dimensional. Each instant, it chooses both the frequency of arrival of new innovations $\lambda_t \in [0, \bar{\lambda}]$ and the quality of new innovations $\theta_t \in [0, 1]$. The arrival intensity of a new innovation $\lambda_t$, determines the Poisson rate at which
innovations arrive. Conditional on an innovation, the number of new product lines that this innovation generates is

$$X_t = \min(Y_t, \bar{p} - P_t) \text{ with } Y_t \sim Bin(n, \theta),$$

where $n$ is an exogenous upper bound on the number of new product lines that can be developed following an innovation, $\theta$ measures the expected quality of the innovation, and $Bin(n, \theta)$ is the binomial distribution. The expected number of new product lines is approximately given by $n\theta$. Therefore, a higher quality $\theta$ leads to a higher expected number of new product lines. Bounding the number of new product lines $X_t$ from above by $\bar{p} - P_t$ ensures that $P_t$ never exceeds $\bar{p}$. The total number of product lines the firm has developed up to time $t$, denoted by $I_t$, evolves as

$$dI_t = X_t dN_t^I,$$

where $dN_t^I$ is a Poisson process with intensity $\lambda_t$.

A firm’s existing product lines can become obsolete because some other firm innovates on a good it is currently producing. In this case, the incumbent producer loses the good from its portfolio due to Schumpeterian creative destruction. Since any firm is infinitesimal, we can ignore the possibility that it innovates on a good it is currently producing. Each product becomes obsolete at an exponentially distributed time with intensity $f$. We call $f$ the rate of creative destruction, that each firm takes as given. Subsection C embeds the individual firm model into an industry equilibrium and endogenizes the rate $f$ of creative destruction. The total number $O_t$ of product lines lost by the firm up to time $t \geq 0$ because of creative destruction evolves as

$$dO_t = dN_t^O,$$

where $dN_t^O$ is a Poisson process with intensity $fP_t$. The total number product lines in a
firm’s portfolio $P_t$ is therefore given by

$$P_t = I_t - O_t.$$ 

A firm with zero product lines exits the economy.

A firm performing R&D with intensity and quality ($\lambda_t, \theta_t$) incurs flow costs $q(P_t, \lambda_t, \theta_t)$. To ensure that shareholders are better off with more product lines we impose that the R&D cost function does not increase too fast in the number of product lines, in that

$$q(p + 1, \lambda, \theta) - q(p, \lambda, \theta) < 1. \quad (1)$$

An incumbent’s operating profit is the profit that comes from the operation of the product lines minus the costs of performing R&D:

$$P_t - q(P_t, \lambda_t, \theta_t).$$

Profits are taxed at the constant rate $\pi > 0$. As a result, firms have an incentive to issue debt to reduce corporate taxes.\(^6\) To stay in a simple time-homogeneous setting, we follow the literature (e.g. Leland (1994), Leland (1998), and Duffie and Lando (2001)) and consider debt contracts that are characterized by a perpetual flow of coupon payments $c$. The firm incurs a proportional cost $\xi$ when issuing debt. The proceeds from the debt issue are distributed on a pro rata basis to shareholders at the time of issuance. Firms whose conditions deteriorate may default on their debt obligations, leading to liquidation. Default risk leads to potential distortions in the firm’s R&D decisions reflecting debt overhang. In addition, at the time of default the firm loses its ability to invest and creditors only recover a fraction $\alpha$ of the cash flow from the product lines in place. When choosing the amount of debt, shareholders balance the tax benefits of debt against its costs. Subsection D allows firms to dynamically change their capital structure.

As in Klette and Kortum (2004), a mass of entrants invests in R&D to become producers

\(^6\)In our model, the main benefit of debt is that it provides tax savings thereby raising the value of an incumbent firm and, therefore, the entrant’s incentives to invest in innovation. We could similarly assume that firms can obtain better financing terms with debt.
upon a successful innovation. When an entrant generates a new innovation, it becomes an incumbent. Similarly to an incumbent, the entrant chooses its R&D intensity $\lambda_t$ and quality $\theta_t$. The entrant has an R&D cost function $q_e(\lambda, \theta)$. Because an entrant has no product lines before becoming an incumbent, its optimal strategy is time-homogenous: $\lambda_t = \lambda_e$ and $\theta_t = \theta_e$. Entrants are all-equity financed before entry. Indeed, issuing debt is suboptimal for these firms because they have no taxable income. After the entrant has an innovative breakthrough and knows how many product lines this breakthrough generates, it has the possibility to issue debt. Entrants pay the entry cost $H$ upon entering the market.

The life cycle of a firm is presented in Figure 2. A firm is at first an all-equity financed entrant, which incurs R&D expenses until it innovates for the first time. At $\tau^e$, the entrant experiences a breakthrough resulting in new product lines and becomes an incumbent. Once the firm enters, it generates profits from its portfolio of products and continues to make R&D decisions, which influences the intensity at which new innovations arrive as well as their quality. This process continues until the firm exits at time $\tau_D$ in case of default or at time $\tau_0$ in case it loses all of its product lines to competitors.
B Optimal Financing and Investment

We start by analyzing the case in which debt policy is static (as in e.g. Leland (1994) and Duffie and Lando (2001)) and consider a firm that initially issues a perpetual debt contract with coupon \( c \). In our model, the value-maximizing level of debt is determined by balancing the tax benefits of debt with issuance, default, and underinvestment costs. That is, the presence of debt can lead to default, which potentially distorts the firm’s R&D decisions.

We solve the model recursively, starting with the value of levered equity for a given financing policy. Since each good generates the same flow of profits, we only need to keep track of the number of goods it produces and the coupon when describing the state of the firm. Let \( \tau_D \) be the time at which the firm defaults. After debt has been issued, shareholders maximize equity value by choosing the firm’s default and R&D policy. As a result, the equity value for a given coupon \( c \) satisfies

\[
E(p, c) = \sup_{\{\lambda_t, \theta_t\}_{t \geq 0}} \mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_0} e^{-rt} (1 - \pi) (P_t - c - q(P_t, \lambda_t, \theta_t)) \, dt \right],
\]

where \( \mathbb{E}_p[\cdot] = \mathbb{E}_0[\cdot|P_0 = p] \), \( \tau_0 \) is the first time the firm has zero product lines, and \( x \wedge y = \inf\{x, y\} \). As shown by equation (2), shareholders receive the after-tax profits from \( P_t \) product lines minus the coupon payments \( c \) and R&D expenses \( q(P_t, \lambda_t, \theta_t) \) until they decide to default. They pick the R&D strategy \( \{\lambda_t, \theta_t\}_{t \geq 0} \) and default time \( \tau_D \) to maximize the equity value. The presence of debt as well as the rate of creative destruction alter shareholders’ incentives to invest in R&D or to continue operations.

From equation (2), it follows that the equity value solves the following Hamilton-Jacobi-Bellman equation

\[
rE(p, c) = \sup_{\lambda, \theta} \left\{ (1 - \pi)(p - c) \right. \\
+ \sup_{\lambda, \theta} \left\{ \lambda \left( \mathbb{E}^\theta \left[ E(\min\{p + x, \bar{p}\}, c) - E(p, c) \right] \right) - (1 - \pi)q(p, \lambda, \theta) \right\} \\
+ fp \left( E(p - 1, c) - E(p, c) \right) \left\}. \right.
\]
where $E^\theta$ takes the expectation over $x \sim Bin(n, \theta)$ and $E(0, c) = 0$. We then have the following result.

**Theorem 1 (Equity Value).** A unique solution to the equity value (2) exists. Equity value is non-decreasing in $p$ and therefore the optimal default strategy is a barrier default strategy

$$
\tau_D = \inf\{t > 0 | P_t \leq p_D\}.
$$

If the optimal level of R&D is interior $((\lambda, \theta) \in (0, \bar{\lambda}) \times (0, 1))$, it solves

$$
E^\theta \left[ E\left(\min\{p + x, \bar{p}\}, c\right)\right] - E(p, c) = (1 - \pi) \frac{\partial q(p, \lambda, \theta)}{\partial \lambda},
$$

$$
\lambda \frac{\partial E^\theta \left[ E\left(\min\{p + x, \bar{p}\}, c\right)\right]}{\partial \theta} = (1 - \pi) \frac{\partial q(p, \lambda, \theta)}{\partial \theta}.
$$

The optimal R&D strategy, if interior, balances the marginal benefits of R&D (left-hand side) and the marginal costs of R&D (right-hand side). The marginal cost depends on the R&D cost function $q(p, \lambda, \theta)$. If an innovation arrives, the increase in equity value is

$$
E^\theta \left[ E\left(\min\{p + x, \bar{p}\}, c\right)\right] - E(p, c),
$$

which is the marginal gain from increasing the arrival rate of innovations $\lambda$. Similarly, higher R&D quality $\theta$ increases the expected number of new product lines when an innovation arrives. The increase in equity value from higher R&D quality $\theta$ (multiplied by the probability of occurrence of an innovation $\lambda$) is

$$
\lambda \frac{\partial E^\theta \left[ E\left(\min\{p + x, \bar{p}\}, c\right)\right]}{\partial \theta}.
$$

The presence of debt in the firm’s capital structure implies that shareholders do not fully capture the benefits of investment, which in turn implies that the level of R&D that maximizes shareholder value is lower in a levered firm. Section II provides a detailed analysis of the effects of debt financing on R&D.

We also perform a comparative statics analysis with respect to the model’s parameters:

**Proposition 1 (Comparative Statics: Equity value).** If $E(p, c) > 0$, equity value is decreasing in the tax rate $\pi$, the coupon $c$, the rate of creative destruction $f$, and the cost $q(p, \lambda, \theta)$ of
performing R&D.

An increase in all of these parameters makes the firm less profitable, thereby reducing the equity value.

After the entrant has an innovative breakthrough and knows how many product lines \( p_0 \) this breakthrough generates, it has the possibility to issue debt. Given the rate of creative destruction \( f \) and shareholders’ optimal R&D \( \{\lambda_t, \theta_t\}_{t \geq 0} \) and default \( \tau_D \) policies, the debt value \( D(p, c) \) is the discounted value of the coupon payments until the time of default plus the present value of the cash flow in default. That is, we have

\[
D(p, c) = \mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_0} e^{-rt} c dt + e^{-r(\tau_D \wedge \tau_0)} (1 - \alpha) \frac{(1 - \pi) P_{\tau_D \wedge \tau_0}}{r + f} \right].
\]  

Finally, we determine the value of an entrant given the rate of creative destruction \( f \). Let \( \tau_e \) be the time at which the entrant has a breakthrough and can develop its first product lines, which happens with intensity \( \lambda_e \). The entrant’s shareholders pick the R&D intensity and quality that maximize their equity value, which consists of the proceeds once there is a breakthrough minus the tax-deductible R&D costs. That is, we have

\[
E^e(f) = \sup_{\lambda_e, \theta_e} \mathbb{E}_0 \left[ e^{-r\tau_e} V(f, \theta_e) - \int_0^{\tau_e} e^{-rt} (1 - \pi) q_e(\lambda_e, \theta_e) dt \right]
= \sup_{\lambda_e, \theta_e} \left( \frac{\lambda_e V(f, \theta_e) - (1 - \pi) q_e(\lambda_e, \theta_e)}{r + \lambda_e} \right),
\]

where

\[
V(f, \theta_e) = \mathbb{E}^{\theta_e} \left[ \sup_{c \geq 0} \{E(p_0, c) + (1 - \xi) D(p_0, c)\} \right],
\]

with \( p_0 = \min(x, \bar{p}) \) and \( x \sim Bin(n, \theta_e) \). As shown by equation (6), shareholders select the coupon that maximizes the value of their claim when entering the industry.

To enter the market, entrants’ shareholders pay the entry cost \( H > 0 \). The free entry condition then implies that

\[
E^e(f) \leq H,
\]
which becomes an equality when there is a positive mass of entrants.

C Industry Equilibrium

This section incorporates the individual-firm decisions into a Schumpeterian industry equilibrium. We look for a Markovian steady state industry equilibrium in which the number of firms and product lines is constant over time. In this industry equilibrium, both incumbents and entrants maximize their equity value. That is, incumbents optimally choose their R&D and default decisions and entrants optimally choose their R&D and capital structure decisions. Given that we look for a Markovian steady state equilibrium, incumbents’ optimal policies are a function of the number of product lines they own and their coupon, which is a function of the number of product lines at entry $p_0$. Entrants’ optimal policies are time-homogenous. Finally, the free entry condition ensures that new entrants continue to enter as long as entry is profitable.

Definition 1. (Industry Equilibrium) The parameters and policies

$$\Psi^* = \{f^*, c^*(p_0), \lambda^*(p|p_0), \theta^*(p|p_0), p^*_D(p_0), \lambda^*_e, \theta^*_e\}$$

are an industry equilibrium if:

1. **Incumbents:** Given the rate of creative destruction $f^*$ and coupon $c^*(p_0)$, incumbents level of R&D $(\lambda^*(p|p_0), \theta^*(p|p_0))$ and default decision $p^*_D(p_0)$ maximize shareholder value.

2. **Entrants:** Given the rate of creative destruction $f^*$, entrants level of R&D $(\lambda^*_e, \theta^*_e)$ and capital structure upon becoming an incumbent $c^*(p_0)$ maximize shareholder value.

3. **Entry:** The free entry condition holds:

$$E^*(f^*) \leq H,$$

and the inequality binds when there is creative destruction $f^* > 0$. 
Figure 3: Steady state equilibrium. This figure gives an example of a steady state distribution in which there is entry.

Figure 3 illustrates an industry equilibrium in which new product lines replace existing ones and entrants replace incumbents that default and exit the industry. The size of the circles indicates the mass of firms of each type. In a steady state equilibrium, the size of these circles is constant over time. Incumbents can move up due to innovations, which generate new product lines, and move down due to creative destruction. Because an innovation can generate more than one product line and the number of product lines generated is random, there are multiple upward flows. In this equilibrium firms exit when they have zero product lines and therefore there is a positive mass of entrants. All industry-wide variables are constant over time, even though individual firms can create new product lines, have existing product lines that become obsolete, and can even exit.

The following theorem establishes equilibrium existence:

**Theorem 2** (Equilibrium Existence). *If Assumption 1 in Appendix B holds then there exists an industry equilibrium $\Psi^*$.*

Under additional conditions, we can establish that all equilibria with entry have the same
rate of creative destruction $f^*$:

**Proposition 2. (Uniqueness of the Rate of Creative Destruction)** If the debt value is strictly decreasing in $f$ then all equilibria have the same rate of creative destruction $f^*$.

The condition that the debt value is strictly decreasing in $f$ ensures that firm value is decreasing in $f$ and that a higher rate of creative destruction makes the firm worse off. Therefore, there can only exist one level of creative destruction for which the free entry condition binds.

Debt increases the rate of creative destruction since it increases firm value, which spurs entry and therefore innovation:

**Proposition 3. (Debt versus No Debt)** Let $f^*_{\text{No Debt}}$ be the equilibrium rate of creative destruction in case firms are restricted to have no debt. Then there exists an industry equilibrium with a rate of creative destruction

$$f^* \geq f^*_{\text{No Debt}}.$$  

**D The Effects of Refinancing**

This section extends the model by allowing firms to dynamically optimize their capital structure. Notably, firms that perform well may releverage to exploit the tax benefits of debt. For simplicity, we assume that firms can only reduce their indebtedness in default.\(^7\) We consider that firms can call their debt at price $\rho(p^I)c$ with $\rho(p^I) > 0$, where $p^I$ is the number of product lines the firm had when it previously issued debt. The ability to buyback the debt for $\rho(p^I)$ implies that we have to keep track of the number of product lines the firm had the last time it issued debt $p^I$. We restrict the firm to refinance at most $K$ times and assume that $c \leq \bar{c}$. In this section, we present the solution for the stationary case when $K \to \infty$. Our results also hold for any finite $K$.

---

\(^7\)While in principle management can both increase and decrease debt levels, Gilson (1997) finds that transaction costs discourage debt reductions outside of renegotiation. Hugonnier, Malamud, and Morellec (2015) show in a Leland-type model that reducing debt is never optimal for shareholders if debt holders are dispersed and have rational expectations. That is, there is no deleveraging along the optimal path. See Admati, DeMarzo, Hellwig, and Pfleiderer (2018) for a similar result in a two-period model.
Define firm value as the equity value plus the debt value minus the issuance cost:

\[ F(p,c,c') = E(p,c,c') + (1 - \xi) D(p,c,c'). \]

The exact definition of the equity and debt value in case the firm can refinance its debt is given below. The payoff to shareholders of restructuring the firm’s debt is given by the value of the firm after refinancing minus the cost of buying back the debt:

\[ \sup_{c' > c} F(p,c',p) - \rho(p') c. \]

This implies that the equity value, with the possibility to dynamically optimize the firm’s capital structure, is given by

\[ E(p,c,c') = \sup_{\{\lambda_t, \theta_t\}_{t \geq 0}} \left\{ \mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_0} e^{-rt}(1 - \pi) (P_t - c - q(P_t, \lambda_t, \theta_t)) dt \right] + \mathbb{E}_p \left[ \mathbb{I}_{\{\tau_R < \tau_D \wedge \tau_0\}} e^{-r \tau_R} \left( \sup_{c' > c} F(P_{\tau_R}, c', P_{\tau_R}) - \rho(p') c \right) \right] \right\}, \]

where \( \tau_R \) is the restructuring time chosen by shareholders. Shareholders receive the revenues generated by the portfolio of products minus the coupon payments, the R&D cost, and corporate taxes until either the firm defaults or changes its capital structure. In default, equity value drops to zero. When refinancing, shareholders repurchase existing debt at price \( \rho(p') c \) and obtain the (after issuance cost) optimal firm value with a larger coupon \( F(P_{\tau_R}, c', P_{\tau_R}) \).

Debt value also takes into account the possibility that the firm refines and is given by:

\[ D(p,c,c') = \mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_0} e^{-rt} c dt + \mathbb{I}_{\{\tau_D \wedge \tau_0 \leq \tau_R\}} e^{-r(\tau_D \wedge \tau_0)} (1 - \alpha) \frac{(1 - \pi) P_{\tau_D \wedge \tau_0}}{r + f} \right] + \mathbb{E}_p \left[ \mathbb{I}_{\{\tau_R < \tau_D \wedge \tau_0\}} e^{-r \tau_R} \rho(p') c \right]. \]

This equation shows that creditors receive coupon payments until either the firm defaults or refinances its debt. When the firm defaults (\( \tau_D \wedge \tau_0 \leq \tau_R \)), creditors get the present value of the firm cash flows net of the proportional default costs \( \alpha \). When the firm refinances its debt (\( \tau_R < \tau_D \wedge \tau_0 \)), creditors get \( \rho(p') c \).
In the numerical analysis, we set $\rho(p')$ such that debt is called at par given that the firm issues debt with the firm value maximizing coupon $c^*(p) \in [0, \bar{c})$. The buyback price $\rho(p')$ therefore solves

$$\rho(p)c^*(p) = D(p, c^*(p), p),$$

where $c^*(p)$ is the optimal coupon given that the firm has $p$ product lines.

The entrant value is the same as in equation (5) with $V(f, \theta_e)$ defined as

$$V(f, \theta_e) = \mathbb{E}^{\theta_e} \left[ \sup_{c \geq 0} \{ E(p_0, c, p_0) + (1 - \xi) D(p_0, c, p_0) \} \right],$$

An industry equilibrium is defined as before, except that firms’ optimal policies additionally depend on the number of product lines the firm had the last time it issued debt $p'$.

In the Appendix, we establish existence of the equity value, which is the equivalent of Theorem 1 in the model with static debt, and existence of an equilibrium

**Theorem 3** (Equilibrium Existence with Debt Refinancing). If Assumption 2 in Appendix C holds, then there exists an industry equilibrium $\Psi^*$ in the model with debt refinancing.

II Model Analysis

This section examines the implications of the model for innovation, financing policy, and industry dynamics. To do so, we calibrate the model to match the observed characteristics of innovation and capital structure policies of an average US public firm, using firms’ financial data from Compustat and the data on firms’ innovation activity from Kogan et al. (2017).

A Parameter values

We first set the interest rate $r$ at 4.2% as in Morelec et al. (2012). We choose a tax rate $\pi$ of 15%, consistent with the estimates of Graham (1996). The bankruptcy cost $\alpha$ is 45%, which is the value estimated by Glover (2016). The cost of debt issuance $\xi$ is set to be 1.36%, consistent with the evidence on debt underwriting fees in Altinkilic and Hansen (2000). We
choose a cost function separable in R&D intensity and quality, as in Akcigit and Kerr (2018). Notably, we assume that:

\[
q(p, \lambda, \theta) = p \left( \beta_i \left( \frac{\lambda}{p} \right)^{\frac{1}{\gamma}} + \beta_q \theta^{\frac{1}{\gamma}} \right),
\]

\[
q_E(\lambda, \theta) = \beta_i \lambda^{\frac{1}{\gamma}} + \beta_q \theta^{\frac{1}{\gamma}},
\]

where \(\beta_q = 2\beta_i\). This specification captures the notion that investment in innovation quality is more expensive than investment in innovation intensity. To obtain the remaining parameter values, we focus on matching several key moments of interest in the data: the mean and variance of the leverage ratio, the mean of the innovation value per patent, and the turnover rate. Firms’ choice of leverage is tightly linked to the parameters governing the R&D cost function \(\beta\) and \(\gamma\). Furthermore, innovation quantity is directly linked to the maximum number of new products per innovation \(n\). These parameters also determine the cost of performing R&D and are thus informative about the innovation value per patent. Lastly, the entry cost \(H\) pins down the turnover rate. Panel A of Table 1 summarizes the baseline values of the parameters.

To compute the data counterparts of the model-implied variables, we use the Kogan, Papanikolaou, Seru, and Stoffman (2017) data on patent quantity and value merged with accounting variables from Compustat. We use the sample period 1980 - 2010. Furthermore, we apply standard Compustat filters and remove firms with negative book equity and market-to-book larger than 15. All variables are then winsorized at 1% and 99% in each fiscal year. Panel B of Table 1 presents the definitions of the moments of interest in the data as well as their model counterparts. We compute the model-implied moments by simulating a panel of firms similar to the ones observed in the data. We simulate a balanced panel of \(N = 15000\) firms over \(T = 15\) years. Firms that exit are replaced with new entrants to keep the panel balanced.

Table 1: Baseline parameter values and definitions of model-implied and data moments.
B Baseline calibration and model-implied moments

We calibrate the static version of the model and report the model-implied variables in Table 2. The numbers suggest that the model succeeds in replicating the magnitude of observed financing and innovation policies. In particular, the average (market) leverage ratio is equal to 20% in the dynamic debt specification and to 25% in the static debt specification, both of which are close to the observed value of 22%. As we will show later on, the relatively low value of leverage in the model is the result of the endogenous rate of creative destruction that disciplines firms’ financing policy and the endogenous investment policy that feeds back in financing decisions. The model also matches the variance of leverage, which equals 1.8% in the data, thus generating sizeable variation in financing policy. The average innovation quality per patent is close to the observed value of 0.5%, and the average innovation quantity (not reported in the table) is 2.26, which is close to the value of 3.95 implied by the data. The model generates a turnover rate of 0.8%, which is close to the observed turnover rate of 1%, reported by Corbae and D’Erasmo (2017).

</table>

Table 2: Baseline calibration of the model.

Table 2 contains the baseline calibration of the model, as well as the model-implied moments in the ‘Dynamic debt’ and ‘No debt’ cases. The table also contains the ‘Fixed f’ specification in which the firm issues debt but the rate of creative destruction f is not determined endogenously, but rather fixed at the level implied by the ‘No debt’ specification. A comparison between the baseline and ‘No debt’ case indicates that debt lowers the outcomes of firms’ R&D investment, and facilitates firm exit by increasing the turnover rate. Comparing the firm values in the baseline static debt case and in the ‘Static debt first-best’ case, in which firms choose their R&D policy by maximizing the firm value rather than the equity value and take the optimal coupon as given in the static debt case, implies an agency cost.
of debt of 0.88%.

The values of the model-implied variables reveal that there are substantial differences between the static and dynamic specification. In particular, when firms are allowed to refinance later on, they adopt lower leverage ratios, as they tend to optimally refinance when they grow larger. This mitigates the debt overhang problem and results in higher levels of R&D innovation than in the static debt case. This translates into larger firms, on average, and thus into a smaller turnover rate than in the static case.

![Figure 4: Distribution of the number of products $p$. The figure shows the distribution of the number of products $p$ in the ‘No debt’ (solid) and ‘static debt’ (dotted) cases.](image)

Debt also has important implications for the size distribution of firms. To illustrate these implications, Figure 4 presents this distribution for the no debt, static debt, and dynamic debt cases. The figure shows that the distribution is positively skewed when firms are allowed to issue debt, which can be attributed to debt overhang changing firms’ incentives to innovate and to the higher turnover rate. The results also imply that the option to restructure debt in the future mitigates the effect of debt on the exit rate, as the size distribution in the dynamic debt case is below that for the static debt case when $p$ is smaller and above when $p$ is larger. Figure 4 demonstrates that debt has a first-order effects on the size distribution of firms.

The results highlight that firms benefit substantially from debt financing: the implied net benefits of debt are around 3.76% of firm value, which is close to the estimates of Korteweg (2010) and van Binsbergen, Graham, and Yang (2010). The benefits of debt vary with firm size: firms with more product lines benefit relatively less from the tax benefits.

Table 3: Comparative statics of selected moments.
Figure 5: **Average tax benefits by** \( p \). The tax benefits of debt are expressed as % of firm value.

### C Interaction of investment and financing policies

In the model, firms determine their investment policy by balancing the benefits and costs associated with each type of R&D investment. Firms increase investment in innovation intensity \( \lambda \) and quality \( \theta \) as long as the marginal benefits outweigh the marginal costs. The marginal benefits follow from the cash flow generated by new product lines and the marginal costs are the cost associated with performing R&D.

Shareholders choose a leverage ratio that balances the marginal benefits and marginal cost of debt. Interest expenses on debt are tax deductible, which gives shareholders an incentive to issue debt. The presence of debt gives shareholders an option to default, which is costly.

Debt also reduces the benefits of innovation to shareholders because part of the benefits of investment accrue to creditors. Therefore, debt distorts innovation incentives and leads to underinvestment. These distortions in innovation policy then feed back into firms’ cash flow dynamics which influences the turnover rate and therefore the optimal leverage choice. Firms’ investment and financing policy are therefore jointly determined. We illustrate these mechanisms below.

### I R&D investment and debt overhang

To illustrate the trade-offs that firms face when determining their investment policy, we first show how they optimally choose their investment in innovation intensity \( \lambda \) and innovation
quality $\theta$ depending on their size, as captured by the number of product lines $p$. Figure 6 shows how debt financing affects both dimensions of the innovation process by plotting the changes in investment in $\lambda$ and $\theta$ as a function of the number of product lines $p$ in two cases. The first case, static debt first-best versus no debt (red dashed line), illustrates the effects of tax benefits. In this case, the first-best uses the rate of creative destruction from the no debt case and the optimal coupon from the static debt case. The second case, static debt first-best versus static debt (solid black line), illustrates the additional effects of agency conflicts between debtholders and shareholders (reflecting debt overhang). In this case, the first-best uses the rate of creative destruction and optimal coupon from the static case.

Figure 6: Changes in optimal R&D investment policies by $p$ due to debt overhang and tax shield. In each case, the static debt first-best is computed using the rate of creative destruction from the no debt or static debt case, respectively, to isolate the effects of debt overhang and tax shield by controlling for distributional changes.

Figure 6 shows that in the first best case in which shareholders can commit to implement the investment policy that maximizes firm value, debt increases R&D investment overall. The effects of tax shield are non-trivial: firms invest up to 3% more in innovation intensity and quality in the static debt first-best case as compared to the no debt case. The fact that these effects tend to become smaller as firm size $p$ increases is due to the fact that larger firms adopt lower leverage. In general, this analysis demonstrates that absent agency conflicts, debt would stimulate investment by incumbents. That is, the (tax) benefits of debt financing outweigh the increase in exit/turnover rate.

Consider next the effects of agency conflicts. Figure 6 shows that when investment de-
cisions maximize shareholder value and firms have debt outstanding, firms not only spend less on R&D overall, but also innovate less on each margin. The effects of debt overhang are substantial in the model. Depending on firm size \( p \) and leverage, in the static debt first-best case firms invest up to 30% more in innovation intensity and quality compared to the baseline case. This distortion, that is solely due to debt, is especially strong for small firms. Again these effects tend to become smaller as firm size \( p \) increases as debt becomes less risky. As a result, wealth transfers to debtholders due to new investment are limited and so are the distortions in investment policy due to debt. Overall, the analysis indicates that debt has first-order effects on firms’ R&D investment policy.

II  Financing policy and investment opportunities

Having documented how firms choose their investment policy, we now illustrate how the trade-offs underlying their choice of leverage vary with their investment opportunity set. Figure 7 shows how leverage is affected by several key parameters describing firms’ investment opportunities: the cost function curvature \( \gamma \), the cost function level \( \beta \), the maximum number of products per innovation \( n \), and the maximum number of product lines \( \bar{p} \).

In the model, higher R&D costs decrease firms’ incentives to innovate, feeding back into the trade-offs that determine their optimal leverage ratio. Higher R&D costs lowers individual firms’ incentives to innovate and therefore a smaller amount of their value comes from growth opportunities. In response, firms increase financial leverage. Figure 7 also shows another important effect concerning the maximum number of product lines \( \bar{p} \) and the maximum number of products per innovation \( n \). When each innovation has the potential of creating more product lines, the potential costs of debt overhang are larger and firms issue less debt. This result is consistent with evidence in Smith and Watts (1992) and Barclay and Smith (1995) that firms with better growth opportunities adopt a lower leverage ratio. The effect of changing \( \bar{p} \) on leverage is more muted. This is due to the fact that \( \bar{p} \) has been chosen large enough so that the effects on firm policies of increasing it further are limited.
Figure 7: **Investment opportunities and financing policy.** The comparative statics were computed for the static debt case and smoothed using a second-order polynomial.

Figure 8: **Debt and the rate of creative destruction.** The comparative statics were computed for the static debt case.

### III Industry equilibrium

Consider next equilibrium dynamics. Firms’ policies affect the rate of creative destruction because they alter firm value, which influences the entry rate. As such, debt plays two
distinctive roles in the model. On the one hand, debt financing leads to underinvestment (i.e. lower R&D) by incumbents, in line with the effects of debt overhang presented earlier (Figure 6). On the other hand, debt leads to a higher rate of creative destruction because it increases firm value, which increases both the entry rate and the aggregate level of R&D.\footnote{It is important to realize that a single firm is infinitesimal and therefore cannot influence the rate of creative destruction by itself, but the actions of all firms can, for example if they all alter their policies when they get the possibility to issue debt.} This effect is illustrated in Figure 8 in which higher tax rate $\pi$—which is associated with higher average leverage—results in a (slightly) higher rate of creative destruction $f$. The figure also shows that in the absence of debt, the equilibrium rate of creative destruction decreases with the tax rate $\pi$, given that higher taxes lower firms’ incentives to innovate, all else equal.

Figure 9: The effects of endogenous rate of creative destruction. The comparative statics were computed for the static debt case. The comparative statics for leverage were smoothed using a second-order polynomial.

In equilibrium, the industry rate of creative destruction and firms’ capital structure de-
cisions are jointly and endogenously determined. To better understand the underlying economic mechanism, Figure 9 shows how changing the cost of innovation $\gamma$ affects equilibrium quantities. The top left panel demonstrates that increasing the cost of innovation $\gamma$ lowers firms’ investment in R&D. Interestingly, when $f$ is fixed, the drop in R&D is much sharper as it does not incorporate the feedback from the industry. Because firms face worse growth opportunities when the cost of R&D investment is high, much of their value is attributable to assets in place. As a result, they increase leverage, as shown by the top right panel of the figure. The effect is again weaker in industry equilibrium as the effects of $\gamma$ on R&D get muted. The drop in innovation quantity and the increase in leverage in turn feedback into the equilibrium rate of creative destruction, as illustrated in the bottom left panel of the figure. In equilibrium, the effect on innovation quantity is first order, leading to a negative relation between $\gamma$ and $f$. This decrease in the rate of creative destruction—and therefore the longer expected productive life of each product line—spurs innovation, partly offsetting the higher innovation costs. Lastly, as illustrated by the bottom right panel, these mechanisms translate to a lower turnover rate as $\gamma$ increases, because the decrease in the rate of creative destruction compensates for the lower levels of innovation. By contrast, with $f$ fixed, the sharp increase in leverage leads to a sharp increase in the turnover rate.

Figure 10: **Leverage and industry concentration.** The comparative statics were computed for the baseline static debt case and smoothed using a second-order polynomial. The measure of concentration is the inverse of the expected mass of firms.

It is also worth mentioning that higher entry cost $H$ results in higher leverage and higher concentration in the industry, as shown in Fig 10. The model is therefore able to replicate
the result in MacKay and Phillips (2005) that firms in more concentrated industries tend to adopt higher leverage ratios.

![Graph showing the relationship between tax rate and % change in f due to debt.](image)

![Graph showing the relationship between cost function curvature and % change in f due to debt.](image)

Figure 11: **Rate of creative destruction and firm characteristics.** The comparative statics were computed for the baseline parameter values.

Finally, we analyze how the rate of creative destruction $f$ is influenced by debt issuance. Each graph in Figure 11 shows how the % change in $f$ between the ‘Static debt’ and ‘No debt’ cases varies along several firm characteristics. The left graph documents that higher taxes result in a larger difference in $f$, which is due to the higher benefits of debt issuance. When the tax rate increases, firms have stronger incentives to have higher leverage, which affects the rate of creative destruction. The right graph shows that the benefits of debt become relatively more important when the cost function curvature $\gamma$ increases, resulting in a larger difference in $f$ between the ‘Static debt’ and ‘No debt’ cases. This happens because the rate of creative destruction decreases with $\gamma$ (see Figure 9), magnifying the effects of debt issuance on $f$.

### III General Equilibrium

This section closes the model in general equilibrium to endogenize the growth rate, labor demand, and the interest rate in the economy. The general equilibrium setup builds on Klette and Kortum (2004). We study a stationary equilibrium with a balanced growth path. This subsection describes the most important details of the general equilibrium framework. Appendix D provides a detailed and formal description.
A Model Description

There is a unit mass of differentiated goods in the economy, which are indexed by \( i \in [0, 1] \), and a representative household with logarithmic preferences. As in Klette and Kortum (2004) or Aghion, Bloom, Blundell, Griffith, and Howitt (2005), the aggregate consumption \( C_t \) follows from a logarithmic consumption aggregator

\[
\ln(C_t) = \int_0^1 \ln(c^i_t) \, di,
\]

where \( c^i_t \) the amount of good \( i \) consumed by the representative household at time \( t \). The logarithm of consumption \( \ln(C_t) \) is used as the numeraire in this economy.

There is a perfectly elastic supply of labor \( L^S \) at a wage \( w \) per unit of labor. All costs in the model come in the form of labor costs, and therefore aggregate production equals aggregate consumption.

Incumbents use labor and installed product lines to produce goods. An improvement in the production technology increases the amount of the consumption good that one unit of labor produces. As in the industry equilibrium framework, there is a leading producer for each type of product. The production technology of good \( i \)'s leading producer is \( q^i_t \) and determines the number of products that one unit of labor produces. A firm that innovates on product \( i \) improves the production technology and becomes the leading producer. We assume that when an innovation arrives at time \( t \), the production technology goes from \( q^i_{t^-} \) to \( q^i_t = (1+\delta)q^i_{t^-} \) with \( \delta > 0 \). A firm that owns the leading production technology for product \( i \) is a monopolist for that good and can choose to supply or not to supply. If the firm supplies the good then it uses one unit of labor to generate \( q^i_t \) units of the product. If it does not supply the good then output and revenues are zero.

The firm can also invest in R&D. As in Klette and Kortum (2004), R&D costs come in the form of labor costs. R&D cost are the wage rate multiplied by the number of hours spend

---

9The model can also be solved with an inelastic supply of labor \( L^S \), in which case the labor supply is exogenous but the wage rate is endogenous.
on R&D. Therefore, for incumbents and entrants their R&D costs are

\[ q(p, \lambda, \theta) = w \ast \tilde{q}(p, \lambda, \theta), \]
\[ q_e(\lambda, \theta) = w \ast \tilde{q}_e(\lambda, \theta). \]

In the industry equilibrium model, entrants pay a fixed entry cost \( H \) to become an entrant. In our general equilibrium model, these fixed costs are replaced by labor costs. An entrepreneur can hire one unit of labor, which costs him \( w \), and that generates an idea with Poisson intensity \( h \). Once the entrepreneur has generated this idea he can become an entrant. Assuming that the rate of creative destruction \( f > 0 \), this implies that the free entry condition becomes \( E^e(f) = \frac{w}{h} \), since in equilibrium the cost and benefits should equate for an entrepreneur

\[ E^e(f)h = w. \]

Finally, we allow the firm to have static debt (or no debt) and assume that there are no debt issuance cost \( \xi = 0 \) and default cost \( \alpha = 0 \) to ensure that all costs come in the form of labor costs.

Under these assumptions, the marginal cost of production is \( \frac{w}{q_t} \). The inverse demand curve determines the price and therefore the profits on product \( i \) are

\[ \pi_i = q_i \left( \frac{1}{q_i} - \frac{w}{q_i} \right) = 1 - w. \]

The profits of a product line is independent of the production technology \( q_t \), which allows us to use the setup and results from previous sections to develop a general equilibrium framework. A firm is the leading producer of \( P_t \) products, each of which generates a profits flow of \( (1 - w) \).

In equilibrium, the growth rate \( g \), labor supply \( L^S \), and the interest rate \( r \) are determined by market clearing in the product and labor market. Consumption grows at the rate

\[ d \ln(C_t) = d \int_0^1 \ln(c_i)di = \ln(1 + \delta) f dt = g dt \] (7)
where $f$ is the rate of creative destruction in the economy, which is caused by innovations by incumbents and entrants.

## B Model Analysis

This general equilibrium setup implies that the interest rate is fixed at the discount rate of the representative household $r$ and that enough labor is supplied such that the labor market clears for a wage $w$. Therefore, the general equilibrium model is equivalent to the industry equilibrium model with the only differences being that the profitability of a single product is now $1 - w$, that all the R&D costs are scaled by $w$, and that the entry cost $H = w/h$. As a consequence, all the results derived in industry equilibrium still hold in general equilibrium.

This also implies that the proposition that shows that creative destruction is higher in an industry equilibrium with debt still holds true in general equilibrium. This higher rate of creative destruction implies that the growth rate is also higher in the presence of debt. The following proposition formalizes this result.

**Proposition 4.** *(Debt versus No Debt)* Let $g^*_{\text{No Debt}}$ be the equilibrium growth rate in case firms are restricted to have no debt. Then there exists an industry equilibrium with a growth rate

$$g^* \geq g^*_{\text{No Debt}}$$

This result follows directly from Proposition 3 and equation (7). In a world with debt, incumbents face debt overhang which lowers investment but the possibility to issue debt increases firm value, which spurs entry and therefore innovation and growth. Importantly, our results are consistent with the evidence in Kerr and Nanda (2009), who examine entrepreneurship and creative destruction following US banking deregulation. Notably, their empirical analysis shows that US banking reforms—that made bank debt widely available and cheaper by increasing competition—brought growth in both entrepreneurship and business closures.
IV Conclusion

This article develops a Schumpeterian growth model of financing and innovation decisions to study the relation between debt financing, innovation and growth. In the model, each firm’s R&D policy influences its risk profile, which affects the firm’s capital structure decisions. Furthermore, a leveraged firm’s investment policy can be altered by debt overhang. Thus, each firm determines its optimal capital structure by trading off the tax benefits of debt against default costs and distortions in R&D investment due to debt financing. We embed the individual firm model into a Schumpeterian industry equilibrium that endogenizes the rate of creative destruction, and derive a steady state equilibrium in which innovating firms introduce new products that replace existing ones, and new entrants replace exiting incumbents. The industry equilibrium results in firms’ individual R&D and capital structure decisions affecting the aggregate level of creative destruction, which feeds back to their individual policy choices.

We show that financing and investment decisions are intertwined at the individual-firm level, with high levels of debt leading to underinvestment in R&D due to debt overhang. As the R&D policy can influence the probability of default, and are themselves influenced by the rate of creative destruction, firms’ capital structure decisions are affected by their innovation policy. Importantly, we demonstrate that debt financing stimulates innovation and creative destruction at the aggregate level. Overall, we illustrate that conclusions reached in a single-firm model can vary substantially from those resulting from a Schumpeterian growth model.

Appendix

The appendix consists of four parts. We solve the static debt case (Theorem 1 and Proposition 1) in Section A. Section B embeds this static debt model into an industry equilibrium (Theorem 2 and Proposition 2). Section C solves the model with refinancing (Theorem 4 and Theorem 3). Section D closes the model in general equilibrium.

A Debt Financing

First, we establish the individual firm results (Theorem 1) and intermediate results that show that the equity value is continuous and decreasing in \( f \) and \( c \) (Lemma 1). Finally, we prove the comparative statics results (Proposition 1).

In the static debt model an incumbent’s coupon is constant. Therefore, we write the equity value as

\[
E(p) = E(p, c)
\]

and use this notation when it does not lead to confusion. Furthermore, the equity value indirectly depends on the parameters \( f \) and \( c \). When necessary, we make this dependence explicit by writing \( E(p|f, c) \).

**Theorem 1 (Equity Value).** A unique solution to the equity value (2) exists. Equity value is non-decreasing in \( p \) and therefore the optimal default strategy is a barrier default strategy \( \tau_D = \inf\{t > 0 | P_t \leq p_D\} \). If the optimal level of R&D is interior \( ((\lambda, \theta) \in (0, \bar{\lambda}) \times (0, 1)) \), it solves

\[
\mathbb{E}^\theta [E(\min\{p + x, \bar{p}\}, c)] - E(p, c) = (1 - \pi) \frac{\partial q(p, \lambda, \theta)}{\partial \lambda},
\]

\[
\frac{\lambda \partial \mathbb{E}^\theta [E(\min\{p + x, \bar{p}\}, c)]}{\partial \theta} = (1 - \pi) \frac{\partial q(p, \lambda, \theta)}{\partial \theta}.
\]

**Proof.** The proof has several steps. First, we establish existence of the equity value. Then we show that it is increasing in the number of product lines \( p \). Finally, we derive the first-order conditions for the internal optimal level of R&D.

1. Equation (3) shows that the equity value for \( p \in \{1, ..., \bar{p}\} \) can be rewritten as

\[
E(p) = \sup_{\theta, \lambda, \tau_D} \left\{ \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+p)f}t(1-\pi)(p - c - q(p, \lambda, \theta))dt \right] + \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+p)f}t (\lambda \mathbb{E}^\theta [E(\min\{p + x, \bar{p}\})] + pf E(p - 1)) dt \right] \right\}.
\]
with $E(0) = 0$. Define $\mathcal{M}(E)$ as the mapping

$$
\mathcal{M}(E) = \sup_{\theta, \lambda, \tau_D} \left\{ \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+pf)t} (1 - \pi) (p - c - q(p, \lambda, \theta)) dt \right] 
+ \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+pf)t} \lambda \mathbb{E}^\theta [E(\min\{p + x, \bar{p}\})] + pf E(p-1) \right] dt \right\}.
$$

Any fixed point of this mapping is bounded from above by $\bar{p}/r$ and from below by zero. Furthermore, the mapping is monotone in $E$ and finally,

$$
\mathcal{M}(E + L) = \sup_{\theta, \lambda, \tau_D} \left\{ \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+pf)t} (1 - \pi) (p - c - q(p, \lambda, \theta)) dt \right] 
+ \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+pf)t} \lambda \mathbb{E}^\theta [E(\min\{p + x, \bar{p}\})] + L \right] dt 
+ \mathbb{E}_p \left[ \int_0^{\tau_D} e^{-(r+\lambda+pf)t} pf (E(p-1) + L) \right] dt \right\},
$$

$$
\mathcal{M}(E + L) \leq \mathcal{M}(E) + \frac{\lambda + \bar{p}f}{r + \lambda + \bar{p}f} L,
$$

because $\lambda \leq \bar{\lambda}$ by assumption. Therefore, the mapping $\mathcal{M}(E)$ satisfies Blackwell’s sufficient conditions for a contraction (see Theorem 3.3 on page 54 in Stokey, Lucas, and Prescott (1989)) and it is a contraction mapping, which implies that a fixed point exists and is unique. The equity value is the fixed point of this mapping.

2. The next step is to show that equity value is non-decreasing in $p$. We do this by showing that having one extra product line improves a firm’s cash flows even if shareholders run the firm as if it does not have this extra product line. Assume today the firm has $p + 1$ product lines and that it separates one product line and runs the firm as if it had only $p$ product lines. The firm receives cash flows from this extra product line until the product line becomes obsolete, the firm’s non-separated number of product lines reaches $\bar{p}$ or zero, or the firm defaults. The firm receives the extra (gross) profits from this separated product line but it also incurs higher R&D costs (since they depend on $P_t$). The equity value of this $p + 1$ firm with a separated product line is given by

$$
E(p) + \mathbb{E}_p \left[ \int_0^{\tau_D(p) \wedge \tau_0(p) \wedge \tau_p(p)} e^{-(r+f)t} (1 - \pi) (1 - q(P_{t} + 1, \lambda_t, \theta_t) + q(P_{t}, \lambda_t, \theta_t)) dt \right],
$$

where $\tau_D(p)$ is the optimal default time of a firm that starts with $p$ product lines, $\tau_0(p)$ is the first time the firm has zero product lines if it starts with $p$ product lines, and $\tau_p(p)$ is the first time a firm with $p$ product lines has $\bar{p}$ product lines. The first term is the cash flows from the $p$ product line firm, and the second term is the cash flow from the separated product line minus the changes in R&D costs. The conditions on the R&D cost function ensure that the second term is non-negative. Furthermore, the optimal
R&D and default strategy followed by a \( p + 1 \) product line firm (weakly) dominates the one chosen by a firm that separates one product line and uses the strategy from a \( p \) product line firm. Therefore,

\[
E(p) \leq E(p) + \mathbb{E}_p \left[ \int_0^{\tau_D(p) \wedge \tau_0(p) \wedge \tau_p(p)} e^{-(r+f)t} (1 - \pi) \left( 1 - q(P_t + 1, \lambda_t, \theta_t) + q(P_t, \lambda_t, \theta_t) \right) dt \right]
\]

\[
\leq E(p + 1),
\]

which shows that the equity value \( E(p) \) is non-decreasing in \( p \). This also implies that a barrier default strategy is the optimal default strategy.

3. Finally, the (internal) optimal levels of R&D should satisfy the first-order conditions that follow from equation (3).

\[\Box\]

**Lemma 1.** The equity value \( E(p|f,c) \) is continuous and non-increasing in \( f \) and \( c \). If \( E(p|f,c) > 0 \) then the equity value is decreasing in \( f \) and \( c \).

**Proof.** We first show that equity value decreases with the rate of creative destruction \( f \).

1. Fix \( f_2 < f_1 \). Let \( P^1_t \) be the number of product lines of a firm facing a rate of creative destruction \( f_1 \). We know that

\[
E(p|f_1) = \mathbb{E}_p \left[ \int_0^{\tau_D^1 \wedge \tau^0} e^{-rt} (1 - \pi) \left( P^1_t - c - q(P^1_t, \lambda^1_t, \theta^1_t) \right) dt \right],
\]

where \( \{\lambda^1_t, \theta^1_t\}, \tau^1_D \) are shareholders optimal strategy given \( f_1 \). The dynamics of \( P^1_t \) are

\[
dP^1_t = dI^1_t - dO^1_t = \max (Y^1_t, \bar{p} - P^1_t) \ dN^1_t - dO^1_t
\]

with

\[
\mathbb{E} [dP^1_t] = \lambda^1_t \mathbb{E}^{\tilde{q}} \left[ \max (Y^1_t, \bar{p} - P^1_t) \right] dt - f_1 P^1_t dt.
\]

2. Define \( \bar{P}^2_t \) as,

\[
d\bar{P}^2_t = dI^1_t - X_t dO^1_t - dH_t,
\]
Given the assumptions on the cost function the equity value satisfies

\[ \tilde{I}_t^1 = \max \left( Y_t^1, \bar{p} - \tilde{P}_t^2 \right) dN_t^1, \]

\[ X_t \sim \text{Bin} \left( 1, \frac{f_2}{f_1} \right), \]

\[ H_t \sim \text{Poisson} \left( f_2 \left( \tilde{P}_t^2 - P_t^1 \right) \right). \]

The construction of \( X_t \) and \( H_t \) implies that,

\[ \mathbb{E}_t \left[ X_t d\tilde{O}_t^1 - dH_t \right] = \frac{f_2}{f_1} f_1 P_t^1 dt - f_2 \left( \tilde{P}_t^2 - P_t^1 \right) dt = f_2 \tilde{P}_t^2 dt. \]

These dynamics imply that \( \tilde{P}_t^2 \) evolves according to the R&D strategy \( \{ \lambda_t^1, \theta_t^1 \} \) given a failure intensity of \( f_2 \). The construction \( \tilde{P}_t^2 \) ensures that

\[ P_t^1 \leq \tilde{P}_t^2. \]

If \( \tilde{P}_t^2 = P_t^1 \) then innovation dynamics are the same \( dI_t^1 = d\tilde{I}_t^2 \). Furthermore, product line failure is higher for \( P_t^1 \) since \( f_2/f_1 < 1 \) and if a product line fails for \( \tilde{P}_t^2 \) then it fails for \( P_t^1 \). Therefore, if \( \tilde{P}_t^2 = P_t^1 \) then \( \tilde{P}_t^2 \geq P_t^1 \). If \( \tilde{P}_t^2 > P_t^1 \) then product line failure can never imply \( \tilde{P}_t^2 < P_t^1 \) since product lines drop by only one. Furthermore, by construction innovation happens at the same time and the number of product lines created for both is either \( Y_t \) or \( \bar{p} \) is reached. This implies that if at time \( t \) product lines are created and \( \tilde{P}_t^2 > P_t^1 \) then \( \tilde{P}_t^2 = \min \left( \tilde{P}_t^2 + Y_t, \bar{p} \right) \geq \min \left( P_t^1 + Y_t, \bar{p} \right) = P_t^1 \).

Therefore, if \( \tilde{P}_t^2 > P_t^1 \) then \( \tilde{P}_t^2 \geq P_t^1 \).

3. Given the assumptions on the cost function the equity value satisfies

\[
E(p|f_1) = \mathbb{E}_p \left[ \int_0^{\tau_D^1 \wedge \tau_0^1} e^{-rt} (1 - \pi) \left( P_t^1 - c - q(P_t^1, \lambda_t^1, \theta_t^1) \right) dt \right] \\
\leq \mathbb{E}_p \left[ \int_0^{\tau_D^1 \wedge \tau_0^1} e^{-rt} (1 - \pi) \left( \tilde{P}_t^2 - c - q(\tilde{P}_t^2, \lambda_t^1, \theta_t^1) \right) dt \right] \\
\leq E(p|f_2).
\]

If the equity value is positive then \( \tau_D \wedge \tau_0 > 0 \), and the second inequality becomes a strict inequality. This shows that \( E(p|f) \) is non-increasing in \( f \) and strictly decreasing in \( f \) when \( E(p|f) > 0 \).

4. The next step is showing that the equity value is continuous in \( f \). The mapping \( \mathcal{M}(E|f) \) is continuous in \( f \). Therefore, for every \( \epsilon > 0 \) there exists a \( \delta > 0 \) such that for \( f' \in (f - \delta, f + \delta) \),

\[
\| \mathcal{M}(E(p|f)|f') - E(p|f) \| = \| \mathcal{M}(E(p|f)|f') - \mathcal{M}(E(p|f)|f) \| < \epsilon.
\]

44
Fix one such $\epsilon$. Define $\mathcal{M}^m(E|f)$ as applying the mapping $\mathcal{M}(\cdot|f)$ $m$ times to $E$. Applying the mapping $\mathcal{M}$ again leads to,

$$\|\mathcal{M}^2(E(p|f)|f') - \mathcal{M}(E(p|f)|f')\| < U\|\mathcal{M}(E(p|f)|f') - E(p|f)\| < U\epsilon.$$ 

where

$$U = \frac{\bar{\lambda} + \bar{p}f'}{r + \bar{\lambda} + \bar{p}f'}.$$ 

This process can be repeated and leads to

$$\|\mathcal{M}^{m+1}(E(p|f)|f') - \mathcal{M}^m(E(p|f)|f')\| < U^m\epsilon.$$ 

Therefore, the distance between $E(p|f)$ and $E(p|f')$ is bounded by

$$\|E(p|f) - E(p|f')\| = \|E(p|f) - \mathcal{M}^\infty(E(p|f)|f')\|$$

$$\leq \sum_{i=0}^\infty \|\mathcal{M}^{i+1}(E(p|f)|f') - \mathcal{M}^i(E(p|f)|f')\|$$

$$< \epsilon \sum_{i=0}^\infty U^i$$

$$= \epsilon \frac{1}{1 - U}$$

$$= \epsilon \frac{r + \bar{\lambda} + \bar{p}(f + (f' - f))}{r}$$

$$= \epsilon \frac{r + \bar{\lambda} + \bar{p}(f + \delta)}{r}.$$ 

Take an $\bar{\epsilon} > 0$ and set

$$\epsilon = \frac{\bar{\epsilon} r}{r + \bar{\lambda} + \bar{p}(f + 1)}.$$ 

Then define $\tilde{\delta} = \min\{\delta, 1\}$. We get that for $f' \in (f - \tilde{\delta}, f + \tilde{\delta})$

$$\frac{r + \bar{\lambda} + \bar{p}(f + (f' - f))}{r} \leq \frac{r + \bar{\lambda} + \bar{p}(f + 1)}{r} = \bar{\epsilon}.$$ 

This implies that for every $\bar{\epsilon} > 0$ there exists a $\tilde{\delta} > 0$ such that for $f' \in (f - \tilde{\delta}, f + \tilde{\delta})$,

$$\|E(p|f) - E(p|f')\| < \bar{\epsilon}.$$ 

Therefore, $E(p|f)$ is continuous in $f$. The same argument shows that $E(p|c)$ is continuous in $c$.

5. The final step is showing that the equity value is non-increasing in $c$ and decreasing if $E(p|c) > 0$. The mapping $\mathcal{M}(E|c)$ is non-increasing in $c$ and non-decreasing in $E$. 

45
Therefore, for a \( c < c' \) we have that

\[
E(p|c) = \mathcal{M}(E(p|c)|c) \\
\geq \mathcal{M}(E(p|c)|c') \\
\geq \mathcal{M}^2(E(p|c)|c') \\
\geq \mathcal{M}^{n>2}(E(p|c)|c') \\
\geq \mathcal{M}^\infty(E(p|c)|c') \\
= E(p|c'),
\]

which proves the result. The first inequality becomes a strict inequality when \( E(p|c) > 0 \), which shows the decreasing result.

\[\square\]

**Proposition 1** (Comparative Statics: Equity value). If \( E(p, c) > 0 \), equity value is decreasing in the tax rate \( \pi \), the coupon \( c \), the rate of creative destruction \( f \), and the cost \( q(p, \lambda, \theta) \) of performing R&D.

**Proof.** The result for \( c \) and \( f \) follows from Lemma 1. Take any other parameter (or the function \( q(p, \lambda, \theta) \)) and call it \( \Xi \). If \( E(p|\Xi) > 0 \) then the mapping \( \mathcal{M}(E|\Xi) \) is decreasing in \( \Xi \) and increasing \( E \). Therefore, we have

\[
E(p|\Xi) = \mathcal{M}(E(p|\Xi)|\Xi) \\
> \mathcal{M}(E(p|\Xi)|\Xi') \\
\geq \mathcal{M}^2(E(p|\Xi)|\Xi') \\
\geq \mathcal{M}^{n>2}(E(p|\Xi)|\Xi') \\
\geq \mathcal{M}^\infty(E(p|\Xi)|\Xi') \\
= E(p|\Xi'),
\]

which proves the result. \[\square\]

**B Industry Equilibrium**

We first establish the existence of an industry equilibrium (Theorem 2). We then derive conditions under which there is a unique rate of creative destruction (Proposition 2).

To establish the existence of an equilibrium, we make the following assumption:

**Assumption 1.** For the firm value, the order of the limit with respect to \( f \) and the supremum over \( c \) can be interchanged:

\[
\lim_{f' \to f} \sup_c \{E(p, c|f') + (1 - \xi)D(p, c|f')\} = \sup_c \lim_{f' \to f} \{E(p, c|f') + (1 - \xi)D(p, c|f')\}.
\]

**Theorem 2** (Equilibrium Existence). If Assumption 1 holds then there exists an industry equilibrium \( \Psi^* \).

**Proof.** The proof has several steps:
1. The first step is showing that the equity value converges to zero when \( f \to \infty \). Assume this is not the case then for some \( p \) we have that \( E(p|f) > 0 \) when \( f \to \infty \). From equation (3) it follows that for any \( p > 0 \) with \( E(p|f) > 0 \)

\[
0 = \frac{-rE(p|f) + (1 - \pi)(p - c)}{f} \\
+ \frac{\max(\lambda, \theta) \left\{ \lambda \left( E^\theta (E(\min\{p + x, \bar{p}\}) - E(p|f)) \right) - (1 - \pi)q(p, \lambda, \theta) \right\}}{f} \\
+ p \left\{ E(p - 1|f) - E(p|f) \right\}.
\]

Given that \( E(p|f) \leq \bar{p}/r \) and \( \lambda \leq \bar{\lambda} \), taking \( f \to \infty \) implies that

\[
0 = p \left\{ E(p - 1|f = \infty) - E(p|f = \infty) \right\}
\]

and therefore that

\[
E(p|f = \infty) = E(p - 1|f = \infty)
\]

for any \( p \) for which \( E(p|f = \infty) > 0 \). Given that \( E(0|f = \infty) = 0 \) this implies that

\[
E(p|f = \infty) = 0,
\]

which is a contradiction. Therefore, the equity value does converge to zero.

2. The debt value also goes to zero when \( f \to \infty \) since the default time and the recovery value in default go to zero. Therefore, firm value \( V(f, \theta) \) and also entrant value \( E_e(f) \) goes to zero as \( f \to \infty \).

3. Define firm value as

\[
F(p_0|f, c) = E(p_0|f, c) + (1 - \xi)D(p_0|f, c).
\]

4. By Lemma 1, equity value is continuous in \( f \) and therefore

\[
\lim_{f' \to f} \|E(p|f, c) - E(p|f', c)\| = 0.
\]

As a result, the dynamics of \( P_t \) will also be the same under \( f \) and \( f' \to f \). If in addition the default threshold is the same then

\[
\lim_{f' \to f} \|D(p|f, c) - D(p|f', c)\| = 0
\]

since the default times will converge. Since the equity value is continuous in \( f \), if the default threshold is not the same then at \( f \) shareholders must be exactly indifferent between default and no default. Take an arbitrary small \( \epsilon \), because the equity value is decreasing in \( c \), for either \( c - \epsilon \) or \( c + \epsilon \) the default threshold under \( f' \to f \) will be the same as the default threshold under \( f \) (and \( c \)). Furthermore, because the equity value

47
is continuous in $f$ and $c$ the dynamics of $P_t$ will be continuous in both as well. This implies that

$$\lim_{\epsilon \to 0} \lim_{f' \to f} \|D(p|f, c) - D(p|f', c \pm \epsilon)\| = 0$$

since the default time will converge. This implies that

$$\lim_{\epsilon \to 0} \lim_{f' \to f} |F(p_0|f, c) - F(p_0|f', c \pm \epsilon)| = 0,$$

5. The previous step shows that for a given $f$, $c$, and $f' \to f$ there exists an $c' = \lim_{\epsilon \to 0} c \pm \epsilon$ such that the firm value is continuous in $f$. This implies that

$$\sup_c F(p_0|f', c) = \sup_{f'} \lim_c F(p_0|f', c) = \lim_{f' \to f} \sup_c F(p_0|f', c).$$

The last step follows from Assumption 1. This shows that $\sup_c F(p_0|f, c)$ is continuous in $f$.

6. The above also implies that

$$V(f, \theta) = \mathbb{E}^\theta \left[ \sup_c \{F(p_0|f, c)\} \right]$$

with $p_0 = \min(y, \bar{p})$ and $y \sim Bin(n, \theta)$ is continuous in $f$ and $\theta$.

7. If there exists an $E^e(f) \geq H$ then the intermediate value theorem ensures existence of an $f$ such that $E^e(f) = H$, which is an industry equilibrium.

8. If for all $f$ $E^e(f) < H$ then entry is never optimal. Given the fact that $P_t$ is non-decreasing for $f = 0$, it follows that for $p > 0$ and $c = 0$ the equity value is positive $E(p|c = 0, f = 0) > 0$. Therefore, a steady state equilibrium exists in which all firms have $\bar{p}$ product lines and no one innovates.

\[ \square \]

**Proposition 2** (Uniqueness of the Rate of Creative Destruction). *If the debt value is strictly decreasing in $f$ then all equilibria have the same rate of creative destruction $f^*$.*

**Proof.** The proof has several steps:

1. First, we show the entrant value is strictly decreasing in $f$. Since the equity value (for any positive value) and debt value are strictly decreasing in $f$, the optimal firm value $V(f, \theta)$ must be strictly decreasing in $f$ as well. Take an $f_1 < f_2$ then

$$V(f_2, \theta) = \mathbb{E}^\theta [E(\min\{x, \bar{p}\}|f_2, c_2) + D(\min\{x, \bar{p}\}|f_2, c_2)]$$

$$< \mathbb{E}^\theta [E(\min\{x, \bar{p}\}|f_1, c_2) + D(\min\{x, \bar{p}\}|f_1, c_2)]$$

$$\leq V(f_1, \theta),$$
where $c_2$ is the firm value maximizing coupon given $\theta$ and $f_2$. Because the entrants value is

$$E^e(f) = \sup_{\{\lambda, \theta\}} \left( \frac{\lambda v(f, \theta) - (1 - \pi)qE(\lambda, \theta)}{r + \lambda} \right),$$

it is also strictly decreasing in $f$.

2. There are now two cases. If $E^e(0) \leq H$ then $E^e(f) < H$ for all $f > 0$ and the only equilibrium rate of creative destruction is $f^* = 0$. If $E^e(0) > H$ then there exists a unique $f^*$ such that

$$E^e(f^*) = H,$$

which is a condition that needs to be satisfied in equilibrium if $f^* > 0$. This proves that any equilibrium must have a rate of creative destruction $f^*$.

\[\square\]

**Proposition 3** (Debt versus No Debt). Let $f_{No \ Debt}^*$ be the equilibrium rate of creative destruction in case firms are restricted to have no debt. Then there exists an industry equilibrium with a rate of creative destruction

$$f^* \geq f_{No \ Debt}^*.$$

**Proof.** The proof has several steps:

1. By assumption the option to issue debt increases shareholder value. This implies that,

$$E^e(f_{No \ Debt}^*) \geq E^e_{No \ Debt}(f_{No \ Debt}^*).$$

2. If $f_{No \ Debt}^* = 0$ then from Theorem 2 it directly follows that there exists an

$$f^* \geq f_{No \ Debt}^*.$$

3. If $f_{No \ Debt}^* > 0$ then

$$E^e(f_{No \ Debt}^*) \geq E^e_{No \ Debt}(f_{No \ Debt}^*) = H.$$

The proof of Theorem 2 shows that the entrant value is continuous in $f$ and that $\lim_{f \to \infty} E^e(f) = 0$. Therefore, there exists an

$$f^* \geq f_{No \ Debt}^*$$

such that

$$E^e(f^*) = H.$$

This $f^*$ is an industry equilibrium.
C Refinancing

First, we establish existence of the equity and debt values (Theorem 4). Next, we establish the existence of an industry equilibrium under Assumption 2 (Theorem 3).

In this appendix we denote by

\[ E_K(p, c, p') \]

the equity value for a firm that can still restructure its debt \( K \) times. The debt value \( D_K(p, c, p') \) and firm value \( F_K(p, c, p') \) are similarly defined. Furthermore, define

\[ E(p, c, p') = \lim_{K \to \infty} E_K(p, c, p'), \]
\[ D(p, c, p') = \lim_{K \to \infty} D_K(p, c, p'), \]
\[ F(p, c, p') = \lim_{K \to \infty} F_K(p, c, p'). \]

**Theorem 4.** The equity and debt values exist. If the optimal level of R&D is internal \(((\lambda, \theta) \in (0, \bar{\lambda}) \times (0, 1))\) then it solves

\[
\mathbb{E}^\theta \left[ E(\min\{p + x, \bar{p}\}, c, p') \right] - E(p, c, p') = (1 - \pi) \frac{\partial q(p, \lambda, \theta)}{\partial \lambda},
\]
\[
\lambda \frac{\partial \mathbb{E}^\theta \left[ E(\min\{p + x, \bar{p}\}, c, p') \right]}{\partial \theta} = (1 - \pi) \frac{\partial q(p, \lambda, \theta)}{\partial \theta}.
\]

**Proof.** We establish existence of the equity and debt value recursively.

1. From Theorem 1 it follows that the equity value for a firm that does not have the option to refinance exists. Therefore, also the debt value exists. Let this equity and debt values define the firm value:

\[ F_0(p, c, p') = E_0(p, c, p') + (1 - \xi)D_0(p, c, p'). \]

The state variable \( p' \) plays no role if the firm cannot restructure.

2. Assume that \( F_{K-1}(p, c, p') \) exists. First, observe the equity value \( E_K(p, c, p') \) does not depend on \( D_K(p, c, p') \) since the price at which the existing debt is bought back is \( \rho(p')c \). The equity value for a firm that has \( K \) restructuring options is

\[
E_K(p, c, p') = \sup_{\{\lambda_t, \theta_t\}_{t \geq 0}, \tau_D, \tau_R} \left\{ \mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_R} e^{-rt}(1 - \pi) (P_t - c - q(P_t, \lambda_t, \theta_t)) dt \right] + \mathbb{E}_p \left[ 1_{\{\tau_R < \tau_D \wedge \tau_R\}} e^{-\tau_R} \left( \sup_{c' > c} F_{K-1}(P_{\tau_R}, c', P_{\tau_R}) - \rho(p')c \right) \right] \right\}.
\]
Given $F_{K-1}(p,c,p')$, this implies that the equity value $E_i(p,c,p')$ is a fixed point of the mapping

$$
\mathcal{M}_K(E) = \sup_{\lambda,\theta,\tau_D,\tau_R} \left\{ \mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_R} e^{-(r+\lambda+p)f} (1 - \pi) \left( p - c - q(p,\lambda,\theta) \right) dt \right] \\
\mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_R} e^{-(r+\lambda+p)f} \lambda \mathbb{E}^\theta \left[ E(\min(p+x,\bar{p}),c,p') \right] dt \right] \\
\mathbb{E}_p \left[ \int_0^{\tau_D \wedge \tau_R} e^{-(r+\lambda+p)f} f p E(p-1,c,p')dt \right] \\
+ \mathbb{E}_p \left[ \mathbb{I}(\tau_R < \tau_D) e^{-(r+\lambda+p)f} (F_{K-1}(p,c',p) - \rho(p')c) \right] \right\}
$$

with $E_K(0,c,p') = 0$. The equity value is bounded from above by

$$
\frac{(1 - \pi)\bar{p} + \pi\bar{c}}{r}
$$

and from below by zero, it is increasing in $E$, and

$$
\mathcal{M}_K(E + L) \leq \mathcal{M}_K(E) + \frac{\bar{\lambda} + f\bar{p}}{r + \lambda + f\bar{p}} L,
$$

which holds even if the firm restructures its debt. Therefore, the mapping $\mathcal{M}_K(E)$ satisfies Blackwell’s sufficient conditions for a contraction, see Theorem 3.3 on page 54 in Stokey et al. (1989), and it is a contraction mapping, which implies that a fixed point exists and is unique. Let $E_K(p,c,p')$ be the fixed point of this mapping.

3. The debt value $D_K(p,c,p')$ follows from the optimal policies of the firm and therefore firm value $F_K(p,c,p')$ also exists. These steps recursively establish existence of the value functions.

4. Optimality of an internal R&D policy implies that they solve the first-order conditions, which shows the last result.

We need the following assumption for the equilibrium existence proof, which generalizes Assumption 1 from the static debt case:

**Assumption 2.** For the firm value, the order of the limit with respect to $f$ and the supremum over $c$ can be interchanged:

$$
\lim_{f' \to f} \sup_c \left\{ E_K(p,c,p|f') + (1 - \xi)D_K(p,c,p|f') \right\} = \sup_c \lim_{f' \to f} \left\{ E_K(p,c,p|f') + (1 - \xi)D_K(p,c,p|f') \right\}.
$$

**Lemma 2.** The entrant value $E_e(f)$ is continuous in $f$.

**Proof.** Continuity is shown recursively.
1. From the proof of Theorem 2 it follows that \( \sup_{c \geq c} F_0(p, c, p^I | f) \) is continuous in \( f \) and \( c \).

2. Assume that \( \sup_{c > c} F_{K-1}(p, c, p^I | f) \) is continuous in \( f \) and \( c \). The mapping \( M_K(E | f) \) is continuous in \( f \). Therefore, for every \( \epsilon > 0 \) there exists a \( \delta > 0 \) such that for \( f' \in (f - \delta, f + \delta) \) we have

\[
\| M_K(E_{K}(p, c, p^I | f) | f') - E_{K}(p, c, p^I | f) \| \\
= \| M_K(E_{K}(p, c, p^I | f) | f') - M_K(E_{K}(p, c, p^I | f) | f) \| \\
< \epsilon.
\]

Fix one such \( \epsilon \). Applying the mapping \( M_K \) again leads to,

\[
\left\| M_{K}^{2}(E_{K}(p, c, p^I | f) | f') - M_{K}(E_{K}(p, c, p^I | f) | f') \right\| \\
\leq U \left\| M_{K}(E_{K}(p, c, p^I | f) | f') - E_{K}(p, c | f) \right\| \\
< U \epsilon.
\]

where,

\[
U = \frac{\bar{\lambda} + \bar{p} f'}{r + \lambda + \bar{p} f'}.
\]

This process can be repeated and leads to

\[
\left\| M_{K}^{m+1}(E_{K}(p, c, p^I | f) | f') - M_{K}^{m}(E_{K}(p, c, p^I | f) | f') \right\| < U^{m} \epsilon.
\]

Therefore, the distance between \( E_{K}(p, c, p^I | f) \) and \( E_{K}(p, c, p^I | f') \) is bounded by

\[
\left\| E_{K}(p, c, p^I | f) - E_{K}(p, c, p^I | f') \right\| = \left\| E_{K}(p, c, p^I | f) - M_{K}^{\infty}(E_{K}(p, c, p^I | f) | f') \right\|
\leq \sum_{i=0}^{\infty} \left\| M_{K}^{i+1}(E_{K}(p, c, p^I | f) | f') - M_{K}^{i}(E_{K}(p, c, p^I | f) | f') \right\|
\leq \epsilon \sum_{i=0}^{\infty} U^{i}
\leq \frac{1}{1 - U}
\leq \epsilon \frac{r + \bar{\lambda} + \bar{p} (f + (f' - f))}{r}.
\]

Take an \( \tilde{\epsilon} > 0 \) and set

\[
\epsilon = \frac{\tilde{\epsilon} r}{r + \bar{\lambda} + \bar{p} (f + 1)}.
\]
then define $\tilde{\delta} = \min\{\delta, 1\}$. We get that for $f' \in (f - \tilde{\delta}, f + \tilde{\delta})$
\[
\frac{r + \lambda + \bar{p}(f + (f' - f))}{r} \leq \frac{r + \lambda + \bar{p}(f + 1)}{r} = \bar{\epsilon}.
\]
This implies that for every $\tilde{\epsilon} > 0$ there exists a $\bar{\delta} > 0$ such that for $f' \in (f - \bar{\delta}, f + \bar{\delta})$,
\[
\|E_K(p, c, p'|f) - E_K(p, c, p'|f')\| < \tilde{\epsilon}.
\]
Therefore, $E_K(p, c, p'|f)$ is continuous in $f$. The same argument shows that $E_K(p, c, p')$ is continuous in $c$.

3. Since the equity value $E_K(p, c, p|f)$ is continuous in $f$, similar steps as in the proof of Theorem 2 show that for $F_K(p_0, c, p_0|f)$ there exists an $\epsilon$ such that
\[
\lim_{\epsilon \to 0} \lim_{f' \to f} |F_K(p_0, c, p_0|f) - F_K(p_0, c \pm \epsilon, p_0|f')| = 0.
\]

4. The previous step shows that for a given $f$, $c$, and $f' \to f$ there exists a coupon $c' = \lim_{\epsilon \to 0} c \pm \epsilon$ such that the firm value is continuous in $f$. This implies that
\[
\sup_{c'} F_K(p_0, c, p_0|f') = \sup_{c} \lim_{f' \to f} F_K(p_0, c, p_0|f') = \lim_{f' \to f} \sup_{c} F_K(p_0, c, p_0|f').
\]
The last step follows from Assumption 2. This shows that $\sup_{c} F(p_0|f, c)$ is continuous in $f$.

5. Applying the previous steps recursively ensures that
\[
\sup_{c'} F_K(p, c', p|f)
\]
is continuous in $f$. This result ensures that
\[
V(f, \theta_E) = \mathbb{E}^{\theta_E} \left[ \sup_{c \geq 0} \{F(p_0, c, p_0)\} \right]
\]
is continuous in $f$ and therefore that the entrant value $E^e(f)$ is continuous in $f$.

\[\Box\]

**Theorem 3** (Equilibrium Existence with Debt Refinancing). If Assumption 2 holds, then there exists an industry equilibrium $\psi^*$ in the model with debt refinancing.

**Proof.** The proof has several steps

1. It follows from Theorem 2 that $F_0(p, c, p')$ converges to zero as $f \to \infty$. Assume $F_{K-1}(p, c, p'|f)$ converges to zero as $f \to \infty$. If $E_K(p, c, p'|f)$ does not converge to zero as $f \to \infty$ then for some $p$ we have that $E_K(p, c, p'|f) > 0$ when $f \to \infty$. This directly
implies that the firm does not restructure for this \( p \). Furthermore, from equation (3) it follows that for any \( p > 0 \) with \( E_K(p, c, p'|f) > 0 \)

\[
0 = -r E_K(p, c, p'|f) + (1 - \pi)(p - c)
\]

\[
+ \max(\lambda, \theta) \left\{ \lambda \left( E^K(\min\{p + x, \bar{p}\}, c, p') \right) - E_K(p, c, p'|f) \right\} + p \left\{ E_K(p - 1, c, p'|f) - E_K(p, c, p'|f) \right\}.
\]

Given that \( E_K(p, c, p'|f) \leq ((1 - \pi)\bar{p} + \pi\bar{c}) / r \) and \( \lambda \leq \bar{\lambda} \), taking \( f \to \infty \) implies that

\[
0 = \pi \left\{ E_K(p - 1, c, p'|f = \infty) - E_K(p, c, p'|f = \infty) \right\}
\]

and therefore that

\[
E_K(p, c, p'|f = \infty) = E_K(p - 1, c, p'|f = \infty)
\]

for any \( p \) for which \( E_K(p, c, p'|f = \infty) > 0 \). Given that \( E_K(0, c, p'|f = \infty) = 0 \) this implies that

\[
E_K(p, c, p'|f = \infty) = 0
\]

which is a contradiction. Therefore, the equity value goes to zero as \( f \to \infty \). The debt value also goes to zero when \( f \to \infty \) since the default time and the recovery value in default go to zero. This result implies that \( F_K(p, c, p') \) goes to zero as \( f \to \infty \). Recursively applying this argument ensures that the entrant value \( E_e(f) \) goes to zero as \( f \to \infty \).

2. If \( \exists f \) such that \( E_e(f) > H \) then Lemma 2, the previous step, and the intermediate value theorem imply there exists an \( f^* \) such that

\[
E_e(f^*) = H,
\]

which is an industry equilibrium.

3. If \( \nexists f \) such that \( E_e(f) > H \) then \( f^* = 0 \) is an industry equilibrium.

D General Equilibrium Setup

In this appendix, we embed our model into a general equilibrium setup. This endogenizes the growth rate of the economy, the labor supply, and the interest rate. The general equilibrium setup is similar to Klette and Kortum (2004) and leads to a stationary equilibrium with a balanced growth path.
Production

There is a unit mass of differentiated goods in the economy, which are indexed by $i \in [0, 1]$. A measure $L^P$ of labor is used for production, a measure $L^{R&D}$ of labor performs R&D, and a measure $L^E$ of labor is used to generate entrants. Labor supply $L^S$ is perfectly elastic, and it receives a wage $w$ per unit supplied in each of these activities.

Incumbent firms use labor and installed product lines to produce goods. An improvement in the production technology increases the amount of the consumption good that one unit of labor produces.

For each type of product there is a leading producer, as in the industry equilibrium model. The production technology of good $i$’s leading producer is $q^i_t$ and determines the number of products that one unit of labor produces.

A firm that innovates on product $i$ improves the production technology and becomes the leading producer. Each innovation is a quality improvement applying to a good drawn at random. The innovation increases the production technology proportionally. That is, when an innovation arrives at time $t$, the production technology increases from $q^i_{t-}$ to $q^i_t = (1+\delta)q^i_{t-}$ with $\delta > 0$.

A firm that is the leading producer for product $i$ is a monopolist for that good and can choose to supply or not supply that good. If the firm supplies the good then it uses one unit of labor to generate $q^i_t$ units of the product. If the firm does not supply the good, its output and profits are zero.\footnote{We can obtain equivalent results when each production line has as production function $q^i_t(l-I_{\{l \geq 1\}} k(l-1))$ where $l$ is the amount of labor used, $k(0) = 0$, $k'(\cdot) > 0$, and the firm produces the maximum amount of the good among production quantities that maximize its profits.}

Let $y^i_t$ be the amount of good $i$ produced at time $t$. As in Klette and Kortum (2004) or Aghion, Bloom, Blundell, Griffith, and Howitt (2005), the aggregate consumption good is produced using a logarithmic aggregator

$$\ln(Y_t) = \int_0^1 \ln(y^i_t) \, di,$$

with $Y_t$ the aggregate production of the consumption good.\footnote{This is a limiting case of the Dixit-Stiglitz aggregator when the elasticity of substitution $\epsilon$ goes to 1}

Innovation

Firms can invest in R&D. Investment in R&D leads to product innovations, which improve the amount of a product that one unit of labor produces. R&D investment costs come in the form of labor costs. Innovation costs are a function of the wage rate multiplied by the
number of hours spend on R&D:

\[ q(p, \lambda, \theta) = w \ast \bar{q}(p, \lambda, \theta). \]  

(8)

Therefore, a firm with \( p \) products that has an R&D policy \((\lambda, \theta)\) requires \( \bar{q}(p, \lambda, \theta) \) units of labor.\(^{12}\) We define the innovation cost function for an entrant in a similar way:

\[ q_E(\lambda, \theta) = w \ast \bar{q}_E(\lambda, \theta). \]

**Default and Entry**

Debt distorts investment in R&D and can lead to default. If a firm with profitable product lines defaults, creditors continue producing these goods until the products become obsolete after which they exit. Furthermore, creditors do not perform R&D and run the firm as an all-equity financed firm. Their expected payoff in default is therefore

\[
\frac{(1 - \pi)P_{\tau_D}(1 - w)}{r + f}.
\]

This setup implies that the debt value is the same as in the industry equilibrium model with \( \alpha = 0 \); see equation (4). In this model, default costs are therefore uniquely related to the distortions in investment policy triggered by default (and debt overhang).

Because firms exit, in a stationary equilibrium there must be entry. As in the industry equilibrium model, entrants have no product lines but perform R&D in the hope of developing innovations, so they can become the leading producer for at least one product. In the industry equilibrium model, entrants pay a fixed entry cost \( H \) to become an entrant. In our general equilibrium model, these fixed costs are replaced by labor costs (as in e.g. Klette and Kortum (2004) or Lentz and Mortensen (2008)). An entrepreneur can hire one unit of labor, which costs him \( w \), and that generates an idea with Poisson intensity \( h \). Once the entrepreneur has generated this idea he can become an entrant. Since in equilibrium the cost and benefits should equate for an entrepreneur, the free entry condition becomes

\[ E^e(f)h = w. \]

**Representative Household**

There is a representative household with logarithmic preferences:

\[
U_0 = \int_0^\infty e^{-rt} \left( \ln (C_t) - wL_t^S \right) dt
\]

\(^{12}\)The condition on the R&D cost that ensures that the equity value is non-decreasing in \( p \), see (1), in the general equilibrium framework boils down to

\[ q(p + 1, \lambda, \theta) - q(p, \lambda, \theta) \leq 1 - w. \]
where $C_t$ is aggregate consumption and $r$ is the discount rate. The representative household’s labor supply $L^S_t$ is perfectly elastic at a wage rate $w$.

**Equilibrium Properties**

Since our model is a closed economy and all costs come in the form of labor costs, consumption equals production for each good $i$, and therefore aggregate consumption and production are also equal

$$C_t = Y_t.$$ 

The logarithm of aggregate consumption $\ln(C_t)$ is the numeraire in this economy. The representative household owns all (financial) assets in the economy and receives all labor income.

Using the logarithm of consumption $\ln(C_t)$ as the numeraire, the representative household’s optimal consumption across goods implies that the price of good $i$ should be

$$\frac{1}{y_i^t} = p_i^t,$$

where the marginal benefit of good $i$ is equal to its marginal cost. The average cost of production are

$$\frac{w}{q_i^t}.$$ 

Therefore, the profits on product $i$ are given by

$$\pi_i^t = q_i^t \left( \frac{1}{q_i^t} - \frac{w}{q_i^t} \right) = 1 - w.$$ 

This result implies that the equity value is as in the industry equilibrium framework (see equation (2)), except that the profit flow from a product line is $1 - w$ instead of 1 and the R&D cost depend on the wage rate $w$ (see equation (8)).

In equilibrium, the growth rate $g$, the interest rate $\tilde{r}$, and the labor supply $L^S$ are determined by market clearing. Since we use the logarithm of consumption as the numeraire, the agent is effectively risk-neutral in the numeraire and therefore,$^{13}$

$$\tilde{r} = r.$$ 

$^{13}$ The risk-free interest rate $\tilde{r}$ should be set such that a household is indifferent between consuming today or tomorrow. Given that there is no aggregate uncertainty, the Hamiltonian for the consumption smoothing problem, with $\tilde{C}_t = \ln(C_t)$ logarithm of aggregate consumption, $\tilde{Y}_t = \ln(Y_t)$ logarithm of aggregate production, $S_t$ savings, and $\kappa_t$ the co-state, is

$$H(\tilde{C}, \tilde{Y}, S, \tilde{r}, \kappa, t) = e^{-rt}u(\tilde{C}) + \kappa[\tilde{r}S + \tilde{Y} - \tilde{C}]$$

where

$$u(\tilde{C}) = \tilde{C} = \ln(C).$$
Consumption grows at a rate of
\[ d \ln(C_t) = d \int_0^1 \ln(y_t^i) di = \ln(1 + \delta) f dt = g dt \]
where \( f \) is the rate of creative destruction in the economy, which results from innovations by incumbents and entrants.

Finally, there is a labor supply \( L^S \) which is used for production \( L^P \), for research \( L^{RkD} \), and to generate entrants \( L^E \):

\[ L^P = 1, \]
\[ L^{RkD} = \int_{\mathcal{F}^I_t} \tilde{q}(P^j_t, \lambda^t_j, \theta^t_j) dj + \tilde{q}_E(\lambda_E, \theta_E) \int_{\mathcal{F}^E_t} dj, \]
where subscript \( j \) indicates firm \( j \), \( \mathcal{F}^I_t \) is the set of active incumbents, and \( \mathcal{F}^E_t \) is the set of active entrants. The labor supply is set such that the labor market clears at a wage \( w \):

\[ L^S = L^P + L^{RkD} + L^E. \]

The utility of the representative household is
\[ U_0 = \int_0^\infty e^{-rt}(\ln(C_0) + gt - wL^S) dt \]
\[ = \frac{\ln(C_0) - wL^S}{r} + \frac{-1}{r} \left[ e^{-rt}g \right]_0^\infty + \int_0^\infty \frac{1}{r} e^{-rt} g dt \]
\[ = r \ln(C_0) + g -rwL^S \frac{1}{r^2}. \]
The higher the growth rate in the economy the higher the representative household’s utility.

The formal equilibrium definition is

**Definition 2** (General Equilibrium). *The parameters and policies*

\[ \Psi^* = \{ g^*, L^{S*}, r^*, f^*, c^*(p_0), \lambda^*(p|p_0), \theta^*(p|p_0), P_D^*(p_0), \lambda^*_e, \theta^*_e \} \]

The optimal solution satisfies the following conditions

\[ H_c(\hat{C}_t, \hat{Y}_t, S_t, \hat{r}_t, \kappa_t, t) = e^{-rt}u'(\hat{C}_t) - \kappa_t = 0, \]
\[ H_S(\hat{C}_t, \hat{Y}_t, S_t, \hat{r}_t, \kappa_t, t) = \kappa_t \hat{r}_t = -\frac{d\kappa_t}{dt}, \]
see Chapter 7 in Acemoglu (2009). Taking the total derivative yields

\[ 0 = -re^{-rt}u'(\hat{C}_t) dt + e^{-rt}u''(\hat{C}_t)d\hat{C}_t - d\kappa_t \]
\[ = -r\kappa_t dt + 0 + \hat{r}_t \kappa_t dt \]
\[ \hat{r}_t = r, \]
which is the Euler equation that the interest rate \( \hat{r}_t \) solves.
are a general equilibrium if:

1. **Incumbents:** Given the rate of creative destruction $f^*$, the interest rate $r^*$, and coupon $c^*(p_0)$, incumbents production decision, level of R&D $(\lambda^*(p|p_0), \theta^*(p|p_0))$, and default decision $p^*_D(p_0)$ maximize their equity value.

2. **Entrants:** Given the rate of creative destruction $f^*$ and the interest rate $r^*$, entrants level of R&D $(\lambda^*_e, \theta^*_e)$ and capital structure upon becoming an incumbent $c^*(p_0)$ maximize their equity value.

3. **Entry:** The free entry condition holds:

$$E^e(f^*) \leq \frac{w}{h},$$

and the inequality binds when there is creative destruction $f^* > 0$.

4. **Labor:** The labor supply $L^{S*}$ ensures that the labor market clears:

$$L^{S*} = L^P + L^{R&D} + L^E$$

for a wage rate $w$.

5. **Growth and interest rate:** The growth and interest rate follow from the Euler equation and the rate of creative destruction:

$$d \ln (C_t) = g^* dt = \ln(1 + \delta) f^* dt,$$

$$r^* = r.$$
